**Abstract**

Investigating causes and consequences of variation in hormonal expression is a key focus in behavioural ecology. Many studies have explored patterns of secretion of the androgen testosterone in male vertebrates, using the challenge hypothesis [Wingfield et al., 1990] as a theoretical framework. Rather than the classic association of testosterone with male sexual behaviour, this hypothesis predicts that high levels of testosterone are associated with male-male reproductive competition but also inhibit paternal care. The hypothesis was originally developed for birds, and subsequently tested in other vertebrate taxa, including primates. Such studies have explored the link between testosterone and reproductive aggression as well as other measures of mating competition, or between testosterone and aspects of male behaviour related to the presence of infants. Very few studies have simultaneously investigated the links between testosterone and male aggression, other aspects of mating competition and infant-related behaviour. We tested predictions derived from the challenge hypothesis in wild male Barbary macaques (*Macaca sylvanus*), a species with marked breeding seasonality and high levels of male-infant affiliation, providing a powerful test of this theoretical framework. Over 11 months, 251 hours of behavioural observations and 296 faecal samples were collected from seven adult males in the Middle Atlas Mountains, Morocco. Faecal androgen levels rose before the onset of the mating season, during a period of rank instability, and were positively related to group mating activity across the mating season. Androgen levels were unrelated to rates of male-male aggression in any period, but higher ranked males had higher levels in both the mating season and in the period of rank instability. Lower androgen levels were associated with increased rates of male-infant grooming during the mating and unstable periods. Our results generally support the challenge hypothesis and highlight the importance of considering individual species' behavioural ecology when testing this framework.

**Introduction**

The challenge hypothesis [Wingfield, Hegner, Dufty, & Ball, 1990], originally proposed to explain temporal variation in testosterone levels in seasonally breeding birds, has served as a powerful framework for investigating the patterns of androgen secretion in male vertebrates. This hypothesis posits that during the breeding season, testosterone levels increase from a pre-breeding baseline to a breeding baseline, sufficient for sperm production and the expression of sexual behavior. Beyond the breeding baseline, the highest levels are expected during periods of acute social challenges associated with reproductive competition, such as when males are mate guarding or establishing dominance relationships [Wingfield et al., 1990]. As such, high testosterone levels should more closely follow measures of reproductive competition, such as aggression, rather than sexual activity itself [Wingfield et al., 1990]. High testosterone levels prime males for competition [Oliveira, 2004], but maintaining such levels is costly, as testosterone increases energy use and mortality, suppresses the immune system, and interferes with paternal care [Wingfield, Lynn, & Soma, 2001]. Therefore, high levels of testosterone are only expected when the adaptive benefits exceed these costs, and low levels should occur at other times.

In support of the challenge hypothesis, elevated testosterone - or more generally androgen - levels during the breeding season, in accordance with increased reproductive competition during this period, have been found in many seasonally breeding primates, e.g. Verreaux's sifaka [*Propithecus verreauxi*: Brockman, Whitten, Richard, & Benander, 2001], golden lion

1  
2  
3 76 tamarins [*Leontopithecus rosalia*: Bales, French, McWilliams, Lake, & Dietz, 2006], ring-  
4  
5 77 tailed lemurs [*Lemur catta*: Gould & Ziegler, 2007], Assamese macaques [*Macaca*  
6  
7 78 *assamensis*: Ostner, Heistermann, & Schulke, 2011], and long-tailed macaques [*Macaca*  
8  
9 79 *fascicularis*: Girard-Buttoz et al., 2015]. On a shorter time scale, elevated androgen levels  
10  
11 80 have been found to be associated with specific measures of reproductive competition. For  
12  
13 81 example, increased levels of androgens are associated with being in the presence of parous  
14  
15 82 estrous females among chimpanzees [*Pan troglodytes*: Sobolewski, Brown, & Mitani, 2013],  
16  
17 83 with time spent mate guarding in long-tailed macaques [Girard-Buttoz et al., 2015] and with  
18  
19 84 consortship in yellow baboons [*Papio cynocephalus*: Onyango, Gesquiere, Altmann, &  
20  
21 85 Alberts, 2013]. By contrast, in male muriquis (*Brachyteles arachnoides*), androgen levels do  
22  
23 86 not differ significantly between mating and non-mating periods, possibly reflecting the low  
24  
25 87 levels of overt aggression over access to mates in this species [Strier, Ziegler, & Wittwer,  
26  
27 88 1999].  
28  
29  
30  
31  
32  
33

34 90 In addition to seasonal changes, androgens have also been positively associated with overall  
35  
36 91 rates of male aggression in ursine colobus monkeys [*Colobus vellerosus*: Teichroeb  
37  
38 92 & Sicotte, 2008], Assamese macaques [Ostner et al., 2011] and olive baboons [*Papio anubis*:  
39  
40 93 Sapolsky, 1983], and also with aggression in specific contexts such as during replacement of  
41  
42 94 resident males in siamangs [*Symphalangus syndactylus*: Morino, 2015], and during incursions  
43  
44 95 of new males into the group among ursine colobus monkeys [Teichroeb & Sicotte, 2008]. In  
45  
46 96 other species, a lack of relationship has been found between androgens and overall rates of  
47  
48 97 aggression, for example in chacma and Guinea baboons [*Papio papio*: Kalbitzer,  
49  
50 98 Heistermann, Cheney, Seyfarth, & Fischer, 2015], and long-tailed macaques [Girard-Buttoz  
51  
52 99 et al., 2015] or between androgens and aggression in specific contexts such as intergroup

100 encounters, for example in siamangs [Morino, 2015] and moustached tamarins [*Saguinus*  
101 *mystax*: Huck, Löttker, Heymann, & Heistermann, 2005].

102  
103 The challenge hypothesis specifically predicts that during periods of social instability linked  
104 to reproductive competition, such as when dominance relationships are being established or  
105 challenged, or group composition is changing, androgen levels will be elevated in dominant  
106 individuals relative to subordinates [Wingfield et al., 1990]. This prediction has been  
107 supported in a wide variety of primates [olive baboons: Sapolsky, 1983; Verreaux’s sifaka:  
108 Brockman et al., 2001; bonobos, *Pan paniscus*: Marshall & Hohmann, 2005; rhesus  
109 macaques, *Macaca mulatta*: Higham, Heistermann, & Maestripieri, 2013; geladas,  
110 *Theropithecus gelada*: Pappano & Beehner, 2014]. A relationship between androgens and  
111 rank has also been found during stable periods in some species where reproductive success is  
112 highly skewed towards high ranking males, [e.g. mandrills, *Mandrillus sphinx*: Setchell,  
113 Smith, Wickings, & Knapp, 2008; yellow baboons: Gesquiere et al., 2011; long-tailed  
114 macaques: Girard-Buttoz et al., 2015], which may reflect the higher ongoing costs of  
115 maintaining high rank, namely responding to aggressive challenges and asserting dominance.  
116 By contrast, in many other species no relationship between rank and androgens exists during  
117 stable periods [e.g. ursine colobus monkeys: Teichroeb & Sicotte, 2008; Assamese macaques:  
118 Ostner et al., 2011; rhesus macaques: Higham et al., 2013; siamangs: Morino, 2015].

119  
120 A further prediction of the challenge hypothesis is that high androgen levels are inhibitory to  
121 paternal care, and such an effect has been documented through both observational association  
122 and experimentation, predominantly in studies of bird species [Wingfield et al., 1990;  
123 Wingfield et al., 2001]. In line with this prediction, androgen levels have been found to be  
124 negatively associated with intensity of paternal care (infant carrying) in siamangs [Morino,

2015], and a decrease in androgens in the birth season has been found in black tufted-ear marmosets (*Callithrix kuhlii*), a species in which males show high levels of infant carrying [Nunes, Fite, & French, 2000]. By contrast, in Geoffroy's marmosets (*Callithrix geoffroyi*) no such relationship has been found between androgen levels and paternal care [Cavanaugh & French, 2013], and in Verreaux's sifaka the presence of infants was not related to variation in androgen levels [Brockman et al., 2001]. Furthermore, it has been suggested that an increase in androgens may reflect the need for aggressive protection against infanticide, for example in the birth season in red-fronted lemurs [*Eulemur fulvus rufus*: Ostner, Kappeler, & Heistermann, 2008], or during extra-group male incursions in ursine colobus monkeys [Teichroeb & Sicotte, 2008].

Here, we test predictions of the challenge hypothesis in wild male Barbary macaques, a species in which this framework has not previously been explored, and which offers an unusual combination of multi-male, multi-female social system, strong breeding seasonality and high levels of male affiliative behavior towards infants. Barbary macaques are considered a relatively "tolerant" species [Thierry, 2000] with a relaxed dominance style [Preuschoft, Paul, & Kuester, 1998] and generally low levels of aggression [Thierry & Aureli, 2006]. Females mate promiscuously during the marked breeding season [Small, 1990], limiting the ability of high ranking males to monopolize mating access [Kuester & Paul, 1992], although mating success is still somewhat skewed towards high ranking individuals [Bissonnette, Bischofberger, & van Schaik, 2011; Young, Hähndel, Majolo, Schülke, & Ostner, 2013]. The mating season represents a time of high male reproductive competition, as evidenced by increased rates of both aggression [Berghänel, Ostner, Schröder, & Schülke, 2011] and male-male inflicted injuries [Kuester & Paul, 1992] during this period. Unusually for a species with a polygynandrous social system, male Barbary macaques frequently interact with infants,

150 carrying, grooming and huddling with them [Whitten, 1987]. These affiliative behaviors are  
151 not considered true paternal care, since males do not preferentially interact with their own  
152 offspring [Ménard et al., 2001; Paul, Kuester, & Arnemann, 1996]; however, they may  
153 benefit males by increasing the likelihood of mating with the mother of the infant in the  
154 subsequent breeding season [Ménard et al., 2001].

156 We explore diverse aspects of the challenge hypothesis, using data on individual males' rates  
157 of aggression and affiliative behavior with infants, and on group levels of mating activity,  
158 collected across breeding and non-breeding seasons (including a period of rank instability).  
159 Specifically, following the challenge hypothesis [Wingfield et al., 1990], we predict that  
160 androgen levels will be (1) higher during the mating season than the non-mating season; (2)  
161 higher during the unstable than the stable period; (3) higher in more dominant individuals  
162 during the unstable but not stable periods (i.e. higher when male rank is overtly under  
163 challenge); (4) positively correlated with rates of aggression as a measure of male  
164 reproductive competition; (5) positively correlated with group-level mating activity as an  
165 alternative measure of male reproductive competition; (6) negatively correlated with rates of  
166 affiliative behavior with infants.

168 **Methods**

169 This study was conducted non-invasively and adhered to standards as defined by the  
170 European Union Council Directive 172 86/609/EEC, and the Ethics Committee of the  
171 University of Roehampton (LSC 15/ 124). Research permission was provided by the Haut-  
172 Commissariat aux Eaux et Forêts et à la Lutte Contre la Désertification of Morocco. This  
173 research adhered to the American Society of Primatologists principles for the ethical  
174 treatment of primates.

175

**176 Study Site and Subjects**

177 This study was conducted on a wild group of Barbary macaques, at a site in Ifrane  
178 National Park (33°25.0N; 005°10.0W) in the Middle Atlas Mountains of Morocco. The study  
179 group (termed the “tourist group”) experiences daily tourist-macaque interactions, including  
180 feeding and taking of photographs [Maréchal et al., 2011]. At the start of the study this group  
181 consisted of 40 individuals, including 12 adult males and 12 adult females, two sub-adult  
182 males, one sub-adult female, six juveniles and seven infants. Age classes were categorized  
183 after Fa [1984]. This group was well habituated to the presence of observers and all adults  
184 and sub-adults could be individually identified. Behavioral and fecal data were collected  
185 between February and December 2012. This period encompassed the end of one mating  
186 season (MS1: 1 – 28 February 2012), followed by a six-and-a-half-month non-mating season  
187 (NMS: 01 March – 15 September 2012) and part of another mating season (MS2: 16  
188 September – 27 December 2012). Mating season was defined as the time between the first  
189 and last ejaculatory copulations, although we excluded from this classification one apparently  
190 complete copulation that occurred 19 days after all other mating activity had ceased, and was  
191 therefore considered anomalous.

192

193 Overall, the present study utilized behavioral data and fecal samples collected from  
194 seven adult males of the tourist group (Table 1). Of the 12 adult males in the group, three  
195 young adults were excluded from data collection due to time constraints, one male died on 05  
196 April 2012, another male was not seen again after sustaining a severe injury on 25 October  
197 2012 and was presumed dead. To maintain a complete dataset across seasons, data from these  
198 latter two males were excluded from analyses. Two males included in analyses were not seen

for some weeks during the mating season: CH was last seen on 24 October and reappeared on 20 November 2012; DO was last seen on 28 October and reappeared on 11 November 2012.

**Behavioral Data Collection**

Behavioral data were collected using continuous focal sampling [Altmann, 1974]. Data were collected five days per week, from approximately 8 am to 5 pm on each study day. One continuous focal sample lasting from 10 to 20 minutes was taken per individual per day and the order of focal samples was randomized and spread throughout the day. Focal samples varied in length, as data were being collected as part of a post event-matched control study related to tourist-macaque interactions [Maréchal, Semple, Majolo, & MacLarnon, 2016], but this variation in focal sample length was not related to variables included in the present analysis. Aggressive behaviors recorded during focal samples were ‘charge’ and ‘physical aggression’. A charge was defined as one monkey moving quickly and forcefully towards another for less than five meters. Physical aggression was defined as one monkey chasing another at high speed for over five meters and/or biting or slapping another monkey. The male-infant care behavior recorded during focal samples was male-infant grooming; both directions of grooming were included, as infants groom males while they are being tended by and/or are huddling with them. The number of unique mating dyads seen per day was recorded as a measure of the intensity of mating activity in the group. Aggressive and displacement interactions between two males, where there was a clear winner and loser, were recorded *ad libitum* and used solely to determine dominance relationships. A displacement was defined as one monkey moving away from another approaching monkey, without the involvement of aggression. For aggressive events, a clear winner and loser were defined when one monkey displayed one or more submissive behaviors (present submission, make

room, give ground or flee) in response to an aggression and without giving a counter aggression.

225

## 226 **Fecal Sample Collection and Hormone Analysis**

227 Fecal samples were collected using methods described by Hodges and Heistermann  
228 [2003]. Briefly, when a monkey was seen defecating without urine or blood contamination,  
229 the fecal sample was collected and homogenized using a latex glove or stick, and solid  
230 objects (e.g. seeds) were removed. Approximately 2-3g was transferred to a collection tube  
231 (Azlon tubes 30 ML HDPE; cat. BWH0030PN). The tube was then stored in a padded box  
232 with ice blocks in the field before being stored in a freezer at  $-20^{\circ}\text{C}$  at the end of the day.  
233 Samples were kept frozen while transported to the UK, and were then stored at  $-20^{\circ}\text{C}$  at the  
234 University of Roehampton. Fecal samples were collected in such a way that, ideally, two  
235 samples were collected from each male in the first half of a month, and two samples in the  
236 second half (see Table 1 for total number of samples per male). Fecal samples were collected  
237 at any time during the day. Individual mean fecal androgen levels from samples collected in  
238 the morning (before 12 pm) were not significantly different from those collected in the  
239 afternoon (after 12 pm), suggesting that time of day had no effect on fecal androgen levels  
240 (morning:  $1616 \pm \text{SD } 807$  ng/g dry fecal weight; afternoon:  $1709 \pm \text{SD } 932$  ng/g dry fecal  
241 weight; Wilcoxon signed rank test:  $N=7$ ,  $Z = -0.845$ ,  $P = 0.398$ ).

242

243 Fecal samples were extracted with 80% methanol using methods previously described  
244 [Heistermann, Finke, & Hodges, 1995]. Extraction efficiency, determined by the recovery of  
245 tritiated estradiol added to the samples before extraction, was  $85.1 \pm 5.2\%$  [Maréchal et al.,  
246 2011]. Extracted fecal samples were assayed for epiandrosterone (fEA), a major metabolite of  
247 testosterone in macaque fecal samples [Möhle, Heistermann, Palme, & Hodges, 2002].

Hormone levels were measured using microtiter enzyme immunoassays in accordance with protocols previously described [Girard-Buttoz, Heistermann, Krummel, & Engelhardt, 2009; Möhle et al., 2002]. The assay was validated for use in Barbary macaques as a measure of androgen levels in fecal samples by comparing the levels of juvenile (fecal samples from another study at the same site) and adult males (samples from present study) (juveniles: N=6, mean=651.7ng EA/g dry fecal weight; adults: N=8, mean=3365.2ng EA/g dry fecal weight; Kruskal-Wallis test,  $p<0.01$ ). This assay has previously been used successfully to measure androgen levels in other macaque species [Girard-Buttoz et al., 2009; Higham et al., 2013; Ostner et al., 2011]. The intra- and inter- assay coefficients of variation for high and low value quality controls were 8.2% and 6.2% (high) and 7.7% and 15.5% (low), respectively. Serial dilutions of test samples had displacement curves parallel to the standard curve. The assay sensitivity at 90% binding was 0.65pg/50µl.

Table 1 here

**Data Analysis**

To compare seasonal differences in androgen levels, we combined hormone data from MS1 and MS2 in all analyses. We quantified rates of aggression (charge and physical aggression) per hour given or received by the focal male toward or from another male during focal observations as a measure of the level of male reproductive competition. As an alternative measure of male reproductive competition, we recorded the number of mating dyads in the group per day. To measure the level of male-infant care, we calculated the percentage of focal observation time that focal males spent in grooming interactions with infants.

273 *Calculating dominance rank and defining stable/unstable periods in the male hierarchy*

274

275 We constructed the male dominance hierarchy, based on 334 dyadic winner-loser  
276 interactions from nine adult males of the study group, by using an elo-rating system  
277 [Neumann et al., 2011]. Data from the two males who died during the study period (see  
278 above) were used in the calculation of elo-ratings but not in further analyses. A plot of the  
279 elo-ratings for each adult male in the group over time is shown in Figure 1. As suggested by  
280 Neumann et al. [2011], elo-ratings before all individuals had at least nine interactions were  
281 considered provisional since they may not reflect an accurate measure of relative rank. For  
282 this reason, elo-ratings before May were not considered when determining rank. Males with a  
283 high rating were considered dominant over those with a lower rating. Elo-ratings were  
284 calculated in R 3.3.2 (R Core Team 2016) using functions adapted from the supplementary  
285 material from Neumann et al. [2011], and used to determine rank at the end of each season, as  
286 outlined below.

287

288 Figure 1 here

289

290 Rankings from May 2012 to the end of July 2012 were stable, with only relatively few  
291 temporary rank reversal interactions involving low ranking males - ranks 5-7, out of 8 (as  
292 well as the seven males in the main analyses, male NU was included here as he was alive for  
293 most of the study period). By contrast, beginning in early August, the three highest ranking  
294 males were involved in rank-reversal interactions. In particular, the male who was ranked  
295 alpha in the beginning of August (NU), rapidly lost rank over the next three months, before  
296 sustaining a severe injury on 25 October 2012 and subsequently disappearing. Then,  
297 beginning at the start of the mating season the rankings of three mid-ranking males also

became unstable. By the end of the study period, it became apparent that four males had permanently changed ranks during the mating season (MS2): the males ranked second (KI) and third (TW) swapped ranks, and the males ranked fourth (FI) and fifth (DO) also swapped ranks. Therefore, study males were given two ordinal (1-7) rankings: one determined from Elo-ratings in mid-September, at the end of the non-mating season, was used for analyses up until this date (i.e. 06 February – 15 September), and one determined at the end of the study in late December, was used for analyses after this date (i.e. 16 September – 27 December). These two male dominance rankings were therefore used in further analyses (Table 1). Note that rank varies for some individuals (KI, TW, FI and DO) across the unstable period, which bridges the two rank periods.

We considered a period of hierarchy instability to have begun on 09 August 2012, when the top ranked male, NU (who was not included in main analyses due to his death during the study period) started losing rank (Fig. 1). The hierarchy remained unstable, meaning there was a relatively high proportion of rank-reversal interactions as well as the disappearance of NU, until the end of the study period (27 December 2012). Therefore, we defined the “unstable period” as being from 09 August – 27 December 2012. By contrast, the preceding five months of the non-mating season had relatively low number of rank reversal interactions. Therefore, we defined the “stable period” as being from 01 March – 08 August 2012.

**Statistics**

All data were found to be non-normally distributed using Kolmogorov-Smirnov tests. We used a set of Generalized Linear Mixed Models (GLMM) to test the influence of different variables on fEA levels. fEA values were log-transformed for analyses so that residuals from

each model met assumptions of normality. All models were fitted with a Gaussian error structure. Each line in the dataset included log fEA levels from a single fecal sample. Because of a time lag of 24 – 36 hours to peak excretion of testosterone metabolites in macaque fecal samples [Möhle et al., 2002], we matched all samples with behavioral data and number of mating dyads from one and two days prior to the day that a fecal sample was collected. If data were available for both days prior to the collection of a fecal sample, then we used the mean of these two days, otherwise only the one available day of data was used. If there were no behavioral data available for either of the previous two days, then data from that fecal sample were not included in the GLMM model. In all models, male ID was included as a random factor.

We ran GLMMs in R 3.3.2 (R Core Team 2016) using the function lmer from the R package lme4 [Bates, Mächler, Bolker, & Walker, 2015]. For each model, we checked assumptions of normality and homogeneity of residuals by visually inspecting q-q plot of residuals and a plot of residuals against their fitted values respectively. In models 2-7 we checked for collinearity of predictor variables by calculating Variance Inflation Factors [VIF: Field, 2005] of a standard linear model, excluding the random effect, using the vif function of R package car [Fox & Weisberg, 2011]. Assumptions of normality were met and VIFs in all models were below 2.31. To test for the significance of the full models, we compared each full model to the correspondent null model which only included the random effect, using the R function ANOVA with argument set to “Chisq”. We determined the significance of the individual predictor variables by a likelihood ratio test by comparing the full with the respective reduced models [Barr, Levy, Scheepers, & Tily, 2013] using the R function drop1. We carried out Kruskal-Wallis and Wilcoxon signed-rank test tests using IBM SPSS Statistics version 21.

348

349 *Relationship of male fEA levels with mating season and with rank stability*

350 We constructed GLMMs to test for an association between log fEA levels and season  
351 (model 1), between log fEA levels and period (model 2), and between log fEA levels and  
352 both season and period (model 3). Note that since MS1 was considered neither a stable nor  
353 unstable period, we were only able to include MS2 in model 3. We used Wilcoxon signed-  
354 ranked test to assess whether there was a difference in mean fEA levels between consecutive  
355 months, i.e. to test for significant temporal changes in androgen levels.

356

357 *Relationship of male fEA levels with rank and behavior*

358 We constructed four GLMMs (models 4-7) to test for the relationship between log  
359 fEA levels and rank, male-male aggression, and male-infant grooming time. Models 4 and 6  
360 explored these relationships during the mating season and unstable period, respectively, and  
361 also tested for a link between log fEA levels and number of mating dyads. Models 5 and 7  
362 tested for relationships during the non-mating season and stable period, respectively.

363

364 **Results**

365 Androgen levels varied markedly over the study period (Fig. 2); levels were consistent from  
366 February to July, with then significant increases from July to August (Wilcoxon signed-rank  
367 test:  $N=7$ ,  $Z = -2.366$ ,  $P < 0.05$ ), and August to September ( $N=7$ ,  $Z = -2.366$ ,  $P < 0.05$ ); levels  
368 in September were not significantly different from October ( $N=7$ ,  $Z = -0.338$ ,  $P = 0.735$ ) but  
369 dropped significantly from October to November ( $N=7$ ,  $Z = -2.366$ ,  $P < 0.05$ ) and stayed low  
370 through December. Strong seasonal variation was also seen in levels of male-male  
371 aggression, with levels markedly higher during the mating season (Fig. 3a). Male-infant

grooming time (Fig. 3b) and number of mating dyads (Fig. 3c), also peaked during the mating season, between October and December.

Figure 2 here

Figure 3 here

Prediction 1. Androgen levels will be higher during the mating season than the non-mating season

GLMM model 1, testing for the relationship between fEA and season, was significantly different from the null model ( $\chi^2 = 4.18$ ,  $df=1$ ,  $P < 0.05$ ). Overall, male fEA levels were significantly higher during the mating season than during the non-mating season (Model 1:  $N=296$ ,  $P < 0.05$ , mean fEA non-mating season= $1464 \pm SE 88$  ng/g dry fecal weight, mean fEA mating season= $1976 \pm SE 186$  ng/g dry fecal weight; increase from non-mating to mating season = 35%; Table 2).

Prediction 2. Androgen levels will be higher during the unstable than the stable period

GLMM model 2, testing for the relationship between fEA and rank stability period, was significantly different from the null model ( $\chi^2 = 56.27$ ,  $df=1$ ,  $P < 0.001$ ). GLMM model 3, testing for the relationship between fEA and season and rank stability period together, was also significantly different from the null model ( $\chi^2 = 64.40$ ,  $df=2$ ,  $P < 0.001$ ). fEA levels were significantly higher during the unstable period than the stable period (Model 2:  $N=270$ ,  $P < 0.001$ , mean fEA stable period= $1156 \pm SE 56$  ng/g dry fecal weight, mean fEA unstable period= $2357 \pm SE 184$  ng/g dry fecal weight; increase from stable to unstable period = 104%; Table 2).

60

397

398 When included in the same model (model 3) mating seasonality and rank stability are

399 correlated with each other ( $r=0.752$ ), meaning that the results of testing predictions 1 and 2

400 presented above, demonstrating significant relationships between mating seasonality and fEA

401 levels and between rank stability and fEA levels, may not be independent. fEA levels were

402 more strongly related (significance and effect size) with rank stability than with mating

403 seasonality (Model 3: Table 2).

404

405 Table 2 here

406

407 Prediction 3. Androgen levels will be higher in more dominant individuals during the

408 unstable but not stable period

409 GLMM models 4 and 6, testing for the relationship between fEA and male-male aggression,

410 male-infant grooming, rank stability, and group-level mating activity during the mating

411 season and unstable period respectively, were significantly different from the null model

412 (Model 4:  $\chi^2 = 21.17$ ,  $df=4$ ,  $P < 0.001$ ; Model 6:  $\chi^2 = 12.70$ ,  $df=4$ ,  $P < 0.05$ ). However,

413 GLMM models 5 and 7 testing for the relationship between fEA and male-male aggression,

414 male-infant grooming and rank stability during the non-mating season and stable period

415 respectively were not significantly different from the null model (Model 5:  $\chi^2 = 2.08$ ,  $df=3$ ,  $P$

416  $= 0.556$ ; Model 7:  $\chi^2 = 6.21$ ,  $df=3$ ,  $P = 0.102$ ).

417

418 Male rank had a significant negative association with fEA levels during the mating season

419 and trended towards significance during the unstable period (Models 4 and 6, Table 3a and

420 3c). Male rank was not significantly associated with fEA levels during the non-mating season

421 and stable period (Models 5 and 7, Table 3b and 3d). In other words, during the mating

season and unstable period, males with high rank generally had higher fEA levels than lower ranked males.

424

Prediction 4. Androgen levels will be positively correlated with rates of aggression as a measure of male reproductive competition

fEA levels were not related to rates of male aggression during the mating season, non-mating season, unstable period, or stable period (Models 4-7, Table 3).

429

Prediction 5. Androgen levels will be positively correlated with group-level mating activity as a measure of male reproductive competition

The number of mating dyads per day was significantly and positively associated with fEA levels during the mating season, but not during the unstable period (Models 4 and 6, Table 3a and 3c).

435

Prediction 6. Androgen levels will be negatively correlated with rates of affiliation with infants

Male-infant grooming time had a significant negative association with fEA levels during the mating season and unstable period; in other words, when fEA levels were higher in these periods, male-infant grooming time was lower (Models 4 and 6, Table 3a and 3c). A positive association was found between male-infant grooming time and fEA levels in the stable period, such that higher fEA levels in this period were linked with higher levels of male-infant grooming (Model 7, Table 3d). However, since the full model for the stable period was not significantly different from the null model, this result must be interpreted with caution. No link was found between male-infant grooming time and fEA levels during the non-mating season (Model 5, Table 3b).

449  
450 **Discussion**

451 The unusual biology of the Barbary macaque, in terms of its combination of social factors,  
452 reproductive seasonality, and male-infant interactions, allowed us to test simultaneously  
453 predictions of the challenge hypothesis relating to reproductive competition, rank stability  
454 and male affiliative behavior with infants. Overall, our findings provide general support for  
455 this hypothesis, and provide new insights into the factors affecting androgen levels among  
456 male primates.

457  
458 Among our study animals, androgen levels began to rise in August, well before the mating  
459 season, peaking six weeks later, at the start of this season, and then declining for the  
460 remainder of its duration. The August rise in androgen levels was coincident with the  
461 beginning of the five-month period of rank instability, with peak levels seen six weeks into  
462 this time. Overall, androgen levels were higher in the mating season and unstable period  
463 compared to the non-mating and stable periods respectively, with the difference being greater  
464 between the stable v. unstable periods than between the non-mating v. mating seasons. There  
465 are two possible explanations for this temporal pattern of change in androgen levels. Firstly,  
466 the coincident increases in androgen levels and instability in the hierarchy indicate these may  
467 be causally related – the challenges of attempting to move up in rank may lead to increases in  
468 androgen levels, increases in androgen levels may lead to males attempting to make such a  
469 move, or both effects may be at work [Wingfield et al., 1990]. Secondly, a rise in androgens  
470 preceding the onset of mating behavior indicates males may undergo physiological  
471 preparation for the mating season, as has been suggested to explain similar pre-mating season

1  
2  
3 472 rises in androgen levels in long-tailed macaques [Girard-Buttoz et al., 2015] and Assamese  
4  
5 473 macaques [Ostner et al., 2011]. It is possible that both processes are important, even though  
6  
7 474 the direct temporal association was stronger between variation in androgen levels and rank  
8  
9 475 stability than between androgen levels and mating seasonality. Rank instability is relatively  
10  
11 476 rare in the study population, but when it occurs it is usually associated with the mating season  
12  
13 477 [Majolo, pers. obs.], as in our study year. In male Barbary macaques, rank instability during  
14  
15 478 the mating season may be due to an increase in coalition formation during this period  
16  
17 479 [Berghänel, Ostner, Schröder et al., 2011], especially by older and lower ranking post-prime  
18  
19 480 males against younger and higher ranking prime males, which de-stabilize dyadic dominance  
20  
21 481 relationships [Berghänel, Ostner, & Schülke, 2011; Bissonnette et al., 2011].  
22  
23  
24  
25  
26

27 483 It is notable that androgen levels peaked at the beginning of the mating season, in the middle  
28  
29 484 of September, and then dropped markedly throughout the rest of this season, during which  
30  
31 485 time levels of mating activity and aggression were at their highest. This drop in androgen  
32  
33 486 levels may be linked to changes in body condition [Pérez-Rodríguez, Blas, Viñuela,  
34  
35 487 Marchant, & Bortolotti, 2006], such that at the start of the mating season males are in optimal  
36  
37 488 body condition and able to sustain high androgen levels, but as physical condition  
38  
39 489 deteriorates over the course of this season androgen levels fall accordingly. In rhesus and  
40  
41 490 Assamese macaques, body condition declines during the mating season [Higham et al., 2013;  
42  
43 491 Ostner et al., 2011] and the same may be true of Barbary macaques, although crude measures  
44  
45 492 of condition - body size or coat quality - did not decline across the mating season in our study  
46  
47 493 animals [Maréchal et al., 2016].  
48  
49  
50  
51  
52

53  
54 495 High ranking males generally had higher androgen levels than subordinates during the mating  
55  
56 496 season and the unstable period, but not outside of these times. These results are in line with  
57  
58

497 studies which found elevated androgen levels in dominant individuals during periods of  
498 social instability in seasonally breeding [Brockman et al., 2001; Higham et al., 2013] and  
499 non-seasonally breeding primate species [Marshall & Hohmann, 2005; Sapolsky, 1983]. The  
500 lack of an association between androgen levels and rank during the period of hierarchy  
501 stability and outside the mating season contrasts with the pattern seen in yellow baboons,  
502 where higher ranked males have higher androgen levels in both stable and unstable periods  
503 [Gesquiere et al., 2011], and in mandrills where androgen levels are related to rank,  
504 independent of rank stability and mating period [Setchell et al., 2008]. This difference may  
505 be explained by the more relaxed dominance style and relatively egalitarian social system of  
506 male Barbary macaques [Preuschoft et al., 1998; Thierry & Aureli, 2006], under which  
507 maintenance of rank does not present a year-round challenge.

508

509 Contrary to the prediction of the challenge hypothesis, we found no link between androgen  
510 levels and rates of aggression in our study species. From the studies that have tested such a  
511 relationship previously in primates, no clear pattern has emerged, with no obvious factor such  
512 as breeding seasonality or mating system differentiating those species in which the prediction  
513 is supported [e.g. Ostner et al., 2011; Sapolsky, 1983; Teichroeb & Sicotte, 2008] from those  
514 in which it is not [e.g. Girard-Buttoz et al., 2015; Kalbitzer et al., 2015]. In Barbary  
515 macaques, despite a marked rise in rates of aggression in the mating season, these rates are  
516 still relatively low; overall, overt aggression may not provide the most appropriate measure of  
517 the levels of male-male competition experienced in our study species, although it is also  
518 possible that the estimated excretion lag time between serum and fecal androgen levels used  
519 in analyses here is too long, or too short. Disentangling rates of aggression, rank instability,  
520 and other measures of competition (including for example coalitions and group take-overs)  
521 across different species may provide a clearer understanding of how androgen levels respond

1  
2  
3 522 to - or are shaped by - male-male reproductive competition. Our finding of a positive  
4  
5 523 relationship during the mating season between androgen levels and mating competition, as  
6  
7 524 determined by group-level mating activity, suggests that the latter provides a more  
8  
9 525 meaningful index of reproductive competition among male Barbary macaques than do rates  
10  
11 526 of aggression. Together, these findings highlight the importance of considering the behavioral  
12  
13 527 ecology of the species in question when seeking the best means to test predictions of the  
14  
15 528 challenge hypothesis in different contexts.  
16  
17  
18  
19

20 529

21  
22 530 We found a negative relationship between androgen levels and rates of male affiliative  
23  
24 531 behavior towards infants in Barbary macaques in both the mating season and the unstable  
25  
26 532 period, in line with the prediction of the challenge hypothesis that testosterone inhibits male  
27  
28 533 care of infants. In contrast, we found a positive relationship between these variables in the  
29  
30 534 stable period although the full model was not significantly different from the null model.  
31  
32 535 While we must be cautious with the interpretation, a number of factors may explain this latter  
33  
34 536 result, each of which is linked to the fact that this period includes the birth season and first  
35  
36 537 few months of infants' lives. Firstly, this is a time when infanticide risk is likely to be higher  
37  
38 538 as infants are still dependent on their mothers, and these females are not yet cycling [Hrdy,  
39  
40 539 1979]; during this period, male affiliative behavior may serve the function of infant guarding,  
41  
42 540 with androgen levels elevated in response to the potential challenge. In support of this idea, it  
43  
44 541 has been found that male Barbary macaques that spent more time carrying infants had higher  
45  
46 542 physiological stress levels [Henkel, Heistermann, & Fischer, 2010]. Alternatively, as male  
47  
48 543 handling may increase access to females in the subsequent mating season [Ménard et al.,  
49  
50 544 2001], males may be competing for access to infants as a form of reproductive competition;  
51  
52 545 this again highlights the importance of considering for each species the different ways in  
53  
54 546 which males compete among themselves.

547  
548 The results of the current study add to our understanding of the complex array of specific  
549 behavioral features that underpin temporal variation in androgen levels - both within and  
550 between individuals - among different primate species. Most predictions derived from the  
551 challenge hypothesis were met. For those that were not, the specific behaviors explored (e.g.  
552 aggression) may not most accurately reflect in this species the nature of male-male challenge  
553 and male-infant care - the fundamental principles on which this hypothesis is based. Careful  
554 consideration of species' behavioral and reproductive ecology is important to generate the  
555 most biologically relevant tests of the challenge hypothesis.

556  
557 **Acknowledgements**

558 We are grateful to Professor Mohamed Qarro (Ecole Nationale Forestière d'Ingénieurs,  
559 Morocco) for his support in the field, and to the Haut Commissariat aux Eaux et Forêts et à la  
560 Lutte Contre la Désertification of Morocco for research permission (Number 235). We are  
561 very grateful to Célia Gobeaut, Laura Martinez Iñigo, Dorsa Amir, Anna Nesbit and Marcelle  
562 Khalil for their help in data collection. We thank also Patrick Tkaczynski for collecting  
563 juvenile fecal samples. Finally, we thank two anonymous reviewers for helpful comments on  
564 a previous version of this manuscript.

Figure legends:

Fig. 1: Elo-ratings for nine adult males in the study group. Each symbol on a line represents when a new dyadic dominance interaction was recorded. A high elo-rating indicates high rank. Rankings before May were considered provisional and not an accurate reflection of relative rank. Note that one male (MI) died on 05 April and another male (NU) disappeared on 25 October and therefore there are no rating interactions for these males after these dates respectively. MS1 (06 Feb – 28 Feb) and MS2 (16 Sep – 27 Dec) = mating season 1 and 2, NMS (01 Mar – 15 Sep) = non-mating season. Stable period: 01 Mar – 08 Aug, unstable period: 09 Aug – 27 Dec.

Fig. 2: Bi-weekly variation in fEA levels of seven adult males across the study period. Depicted are means  $\pm$  SE. MS1 (06 Feb – 28 Feb) and MS2 (16 Sep – 27 Dec) = mating season 1 and 2, NMS (01 Mar – 15 Sep) = non-mating season. Stable period: 01 Mar – 08 Aug, unstable period: 09 Aug – 27 Dec.

Fig. 3: Bi-weekly variation in: (a) male-male aggression per hour; (b) male-infant grooming time; (c) daily mating dyads. Depicted are means  $\pm$  SE. MS1 (06 Feb – 28 Feb) and MS2 (16

Sep – 27 Dec) = mating season 1 and 2, NMS (01 Mar – 15 Sep) = non-mating season. Stable period: 01 Mar – 08 Aug, unstable period: 09 Aug – 27 Dec.

For Peer Review

**TABLE 1: A summary of focal hours and hormonal data collected per study subject (excluding NU who disappeared part way through the second period (P2). Some males had different ranks for different parts of the study period (1 = most dominant, 7 = most subordinate): P1 = 6 Feb - 15 Sep 2012. P2 = 16 Sep - 27 Dec 2012.**

Male ID	Rank P1 (P2)	Observation days	Fecal samples	Mean fEA (ng/ g dry fecal weight)	Observation time (hours)
GA	1 (1)	200	44	1337	38.5
KI	2 (3)	193	42	1764	36.1
TW	3 (2)	201	43	3497	37.7
FI	4 (5)	201	41	1659	37.2
DO	5 (4)	193	41	1249	36.2
CH	6 (6)	180	41	1346	33.8
PE	7 (7)	198	44	829	31.5
Total			296		251.0

**TABLE 2: Summary of GLMM results for the relationship between fEA with (a) season, (b) period and (c) both season and period. In all models: response = log fEA, Number of males = 7, random effect = monkey ID**

	GLMM estimate	SE	$\chi^2$	df	P-value
<b>(a) Model 1: Season (N=296)</b>					
Intercept	3.138	0.068	-	-	-
Season (non-mating, mating)	-0.062	0.030	4.18	1	0.041
<b>(b) Model 2: Period (N=270)</b>					
Intercept	3.010	0.064	-	-	-
Period (unstable, stable)	0.222	0.028	56.27	1	< 0.001
<b>(c) Model 3: Season and period (N=270)</b>					
Intercept	2.884	0.077	-	-	-
Season (non-mating, mating)	0.127	0.044	8.12	1	0.004
Period (unstable, stable)	0.313	0.042	50.49	1	< 0.001

**TABLE 3: Summary of GLMM results for (a) the mating season, (b) the non-mating season, (c) the unstable period and (d) the stable period. In all models: response = log fEA, Number of males = 7, random effect = monkey ID**

	GLMM estimate	SE	$\chi^2$	df	P-value
<b>(a) Model 4: Mating season (N=99)</b>					
Intercept	3.402	0.115	-	-	-
Aggression/ hour	0.037	0.031	1.32	1	0.251
Male-infant grooming (% time)	-0.483	0.227	4.40	1	0.036
Mating dyads/ day	0.033	0.011	7.56	1	0.006
Rank	-0.084	0.025	8.12	1	0.004
<b>(b) Model 5: Non-mating season (N=162)</b>					
Intercept	3.211	0.121	-	-	-
Aggression/ hour	0.005	0.011	0.19	1	0.664
Male-infant grooming (% time)	0.243	0.317	0.58	1	0.445
Rank	-0.033	0.027	1.39	1	0.239
<b>(c) Model 6: Unstable period (N=118)</b>					
Intercept	3.506	0.125	-	-	-
Aggression/ hour	0.004	0.014	0.10	1	0.754

Rank	-0.031	0.027	1.17	1	0.278

Research highlights:

- Androgen levels peaked at start of the mating season.
- Androgens positively related to mating competition and negatively related to male-infant grooming during the mating season.
- Androgen levels higher in dominant males during rank instability
